ABSTRACT

Reflux symptoms are commonly encountered in clinical practice. The vast majority of patients with typical reflux symptoms and no red flags may be placed on an empirical course of proton pump inhibitors (PPI). Patients with red flag findings require prompt further evaluation. Patients with symptoms not responding to PPI will require review of their compliance to PPI, clarification on which symptoms remain unresponsive and further evaluation in a directed manner.

Keywords: Gastroesophageal reflux disease; Proton pump inhibitors; Ambulatory esophageal pH monitoring; Refractory reflux symptoms;

INTRODUCTION

Gastroesophageal reflux disease (GERD) refers to the abnormal reflux of gastric contents that gives rise to chronic symptoms of heartburn, regurgitation, or injury to the esophagus and contiguous organs of the upper aerodigestive tract. Symptoms suggestive of GERD are common and increasing in prevalence in Singapore. While the classic symptoms of GERD are usually readily recognised and satisfactorily treated with acid-suppressive medication, a substantial proportion of patients continue to have symptoms that are refractory to acid-suppressive medication and this is a common reason for a visit to a gastroenterologist. This review outlines a practical approach for patients who present with reflux symptoms and the further management of patients who have persistent symptoms that are unresponsive to acid-suppressive medication.

ARE THE SYMPTOMS CONSISTENT WITH GASTROESOPHAGEAL REFUX DISEASE?

The classic symptoms of GERD are heartburn and acid regurgitation. Heartburn refers to the retrosternal burning sensation that rises towards the neck. Heartburn is relieved by antacids and milk, and tends to occur after meals and upon lying down, typically at night. Regurgitation refers to the backflow of gastric contents, which are typically sour or bitter, into the chest or mouth.

Less common symptoms of GERD would include chest pain, dysphagia (sensation of food sticking in the chest), odynophagia (painful swallowing) and water brash (hypersalivation). These latter symptoms, though consistent with GERD, should prompt a careful assessment for an alternate cause — for example, cardiovascular disease in chest pain, oesophageal cancer in dysphagia and oesophageal ulcer in odynophagia.

Patients presenting with the following symptoms may require a more nuanced history taking to identify an alternate cause for their symptoms that require a different management strategy. Belching (“burping”) refers to the retrograde passage of gas out of the mouth. It is a physiological phenomenon that allows for venting of the stomach when it is distended by swallowed gas after a meal. Belching may also occur in patients with GERD and functional dyspepsia. Patients who present with repetitive belching as an isolated complaint have an alternate mechanism for their belching, where air is sucked into the oesophagus and expelled without reaching the stomach. This is a condition known as supragastric belching. Patients are reassured of the benign nature of their belching, advised to avoid gum chewing, smoking, drinking carbonated beverages, and gulping their food and liquids. They may also be treated with diaphragmatic breathing (see below).

Bloating is often encountered in patients presenting to the primary care physician but it is not a symptom of GERD. In patients with bloating, any relation to meals or defaecation and a concomitant change in stool habits should be elicited to determine if the patient presenting with bloating has dyspepsia or irritable bowel syndrome. This would direct further evaluation and management.

Any Red Flags to Warrant Early Endoscopy?

Diagnostic tests are unnecessary in most patients with GERD who present with typical symptoms of heartburn and regurgitation. However, patients exhibiting red flags such as dysphagia, odynophagia, anorexia, weight loss, GI bleeding, or iron-deficiency anaemia should be referred for further GI evaluation. Patients with chest pain should have a cardiac evaluation before it is ascribed to GERD. Further investigations need to be performed in patients with red flags and those with symptoms that do not respond to PPI.

Empirical Trial of Proton Pump Inhibitors

Patients who present with typical symptoms of retrosternal heartburn and acid regurgitation in the absence of any red flags may be treated empirically with acid suppressive medication such as proton pump inhibitors (PPI). Complete resolution of typical symptoms with PPI would be a practical means of diagnosing GERD. As GERD is a chronic disease, symptoms may recur upon cessation of PPI and this would suggest a need for long-term management.
DEALING WITH THE PATIENT WITH REFLUX SYMPTOMS THAT ARE REFRACTORY TO ACID SUPPRESSION

Patients with refractory reflux symptoms refers to those whose symptoms fail to respond partially or completely to a standard dose of PPI after a sufficient period of therapy, typically 8 weeks. A substantial proportion of patients with reflux symptoms continue to have symptoms that remain unresponsive to PPI.

While PPIs are currently the most effective acid-suppressive therapy for GERD, we now recognise that PPIs vary in their efficacy for treating the individual manifestations of GERD. The response of a specific GERD manifestation is dependent on the degree to which that manifestation is related to acid. PPIs are most effective at achieving mucosal healing in patients who have oesophageal mucosal erosions on endoscopy, a subset of GERD known as erosive oesophagitis. However, the rate of complete symptom relief with a PPI is less than the rates of mucosal healing. Heartburn, the most characteristic reflux symptom, is the symptom that responds best to acid suppression. PPIs are less effective at treating regurgitation as PPIs increase the pH of gastric contents but do not eliminate the backflow of gastric juice that accounts for regurgitation.

We now also recognise that patients with persistent reflux symptoms refractory to PPI treatment often do not have GERD but are a heterogeneous group with a diverse range of conditions that can account for their symptoms (Table 1).

Further evaluation of the patient with refractory symptoms thus focuses on the following principal considerations:

1. Reviewing and reinforcing compliance to PPIs which are the most effective medication for GERD.
2. Carefully eliciting which symptom is not responding to a PPI as this may give clues to the underlying condition.
3. Evaluating for an alternate cause in a directed manner.

PPI Compliance

PPIs work by inhibiting the hydrogen-potassium ATPase pump in the gastric parietal cells. PPIs inhibit actively secreting proton pumps, hence they are most effective in reducing acid secretion when they are taken before meals, especially before breakfast. A large proportion of patients do not adhere to pre-meal dosing, hence optimising compliance should be undertaken to address an incomplete symptom response to a PPI. In patients who continue to be symptomatic, doubling the dose of PPI or switching PPIs has limited benefits. The addition of raft-forming agents (e.g. alginates) may improve heartburn in some patients.

Diagnostic Investigations in the PPI-refractory Patient

Further evaluation of the patient with refractory reflux symptoms involves oesophagogastroduodenoscopy (OGD) and ambulatory pH testing and oesophageal manometry in selected instances.

Oesophagogastroduodenoscopy

Endoscopic examination of the upper GI tract is usually performed as the next step in evaluation. OGD allows for the detection of non-oesophageal conditions (e.g. peptic ulcers) which may present with reflux symptoms. OGD enables the detection of non-reflux oesophageal conditions such as drugs, infectious and eosinophilic oesophagitis, as well as oesophageal cancer. These conditions often have distinct endoscopic findings and diagnosis is confirmed on oesophageal biopsies. OGD also provides information on the severity of GERD (i.e. eosinophilic oesophagitis) and the presence of complications such as Barrett oesophagus and oesophageal strictures. The presence of these findings would direct further management according to the etiology.

Barium contrast studies

Barium contrast studies are not recommended for the diagnosis of GERD as they have limited utility in detecting mucosal changes of GERD, and the demonstration of reflux on barium studies is not a reliable test for the diagnosis of GERD. It may be useful in selected patients for the demonstration of strictures and hiatal hernia, and in patients with suspected achalasia who are unwilling to undergo oesophageal manometry.

Ambulatory oesophageal pH monitoring

Ambulatory oesophageal pH monitoring provides a means to quantify acid exposure in the distal oesophagus as an objective measure of GERD. It entails placing a probe with a pH sensor through the patient’s nose into the distal oesophagus. It transmits pH measurements from the distal oesophagus to a recorder worn on the person. These recorders have buttons that enable patients to record meals, symptoms events, and changes in posture. This recording is performed over a 24-hour period. In patients who are unable to tolerate a nasal tube, wireless pH monitoring exists that entails attaching a pH capsule into the distal oesophagus during endoscopy. Generally, pH testing is performed when the patient is not taking any acid-suppressive medication.

The vast majority of patients with reflux symptoms will not require any pH testing. Testing is usually performed for preop-
is thus an uncommon finding in patients with reflux symptoms that have already received treatment with PPI prior to OGD. Hence the presence of erosive oesophagitis on OGD should prompt the following considerations. The patient’s compliance to the PPI should be reviewed and reinforced. Alternate non-reflux aetiologies of oesophagitis such as medications (bisphosphonates, tetracyclines) and infections (cytomegalovirus, Candida, herpes) may need to be entertained in selected instances though most of these conditions have distinct endoscopic appearances that differentiate themselves from erosive oesophagitis due to GERD. Acid suppression may need to be escalated and anti-reflux surgery (i.e. fundoplication) may be considered in selected instances of patients with erosive oesophagitis.

**Persistent regurgitation**

Regurgitation, as a symptom of GERD, is less responsive to acid-suppressive medication than heartburn. Fundoplication may be considered in selected GERD patients who have troublesome regurgitation. However, it is imperative that several conditions are excluded before fundoplication is undertaken to avoid an unsatisfactory outcome. An attempt must be made to determine whether the patient indeed has regurgitation or vomiting. The latter is characterised by the presence of nausea and forceful abdominal contractions which are absent in regurgitation. Vomiting entails an entirely different diagnostic work-up that encompasses gastrointestinal, intra-cranial and systemic diseases. In practice, the distinction between vomiting and regurgitation may not always be easily made and a broader list of differential diagnoses needs to be entertained that encompasses both symptoms in some patients.

In patients deemed to have regurgitation one has to exclude achalasia and rumination syndrome before fundoplication is considered. Achalasia is an uncommon disease characterised by absent oesophageal peristalsis and failure of relaxation of the LES. Classic symptoms include dysphagia, regurgitation, chest pain and weight loss. The regurgitation of bland retained oesophageal contents in achalasia may in some instances differentiate it from the sour acid regurgitation in GERD. Achalasia is diagnosed on oesophageal manometry. In patients with equivocal findings, barium contrast studies may be required as well to diagnose achalasia. OGD is performed in every patient with achalasia to exclude gastroesophageal cancers and other conditions that may mimic achalasia (i.e. pseudoachalasia). Treatment of achalasia is directed at mechanical disruption of the LES either by pneumatic dilatation or myotomy. The latter may be performed surgically or endoscopically.

Rumination syndrome is a benign condition characterised by effortless regurgitation of recently ingested food into the mouth followed by remastication and swallowing back or spitting out. The regurgitant consists of recently swallowed food that can still be recognised by the patient and regurgitation typically occurs in the context of a meal. It does not affect sleep, unlike regurgitation in GERD which may occur as a nocturnal event affecting sleep. Rumination syndrome can affect adults of both gender across the age spectrum and is often misdiagnosed due to a lack of awareness of this benign condition. Patients are managed by reassurance, explanation of the condition and behavioral therapy which focuses on learning to recognise when
ruminations and habit reversal with diaphragmatic breathing techniques. Ruminations involve contraction of the abdominal wall muscles. Diaphragmatic breathing entails breathing in and out with the abdominal muscles which is incompatible with the abdominal wall contractions required for ruminations to occur. Consistent practice of diaphragmatic breathing thus counters the act of rumination.

CONCLUSION

This review outlines a practical approach to the patient with reflux symptoms. The majority of patients with typical reflux symptoms and no red flags may be placed on an empirical course of proton pump inhibitors (PPIs). Patients with red flag findings require prompt further evaluation. Patients with symptoms not responding to PPI will require further evaluation which would encompass a review of their compliance to PPI, clarification on which symptoms remain unresponsive, and further evaluation in a directed manner.
